I. INTRODUCTION

I implemented an IoT system that monitors the temperature of an house, to prevent useless HVAC consumption, detecting it by rapid temperature changes. Reducing energy usage has good environmental reasons and also saves money on the bills. In this report, I show the components and the structure of the system I've realized. Then I show the experimental setup and the consequent results I've obtained; at the end, I present some thoughts on them.

II. PROJECT'S ARCHITECTURE

The system is composed by an ESP-WROOM-32 board linked to two DHT22 sensors (one placed inside the house and one outside) and to a LED.

The board periodically collects indoor and outdoor temperature values. They are constantly analysed: if the indoor temperature values rapidly change (approaching the values of outdoor one) the LED is temporarily turned on, thus showing an alarm signal to the user. In this way, if the temperature change is caused by, e.g., an open window, you can save unnecessary HVAC waste. At the beginning, based on all past temperature data, the system predicts some future temperature values.

The collected temperature data are continuously sent to a gateway, that stores them, together with the alarm triggers and the forecasted temperature values, on a local time-series database. All data are interactively visualized by a local web application, that shows them by means of charts.

III. PROJECT'S IMPLEMENTATION

A. Data acquisition

I made the `data_acquisition.ino` file to program the ESP32 board. I use the `Thing.CoAP` library to make the board act as a CoAP server and the `PubSubClient` library to make it act as a MQTT subscriber.

Through the CoAP protocol, the ESP32 is able to send the latest collected indoor and outdoor temperature value, when asked.

Through the MQTT protocol, the board can receive some commands: to start or stop the sensors reading (at the beginning they are off), to change the interval between consecutive sensors readings — in both cases you can decide for just one of the two sensors — and to turn on or off the LED. My laptop acts as a MQTT broker, through Mosquitto.

B. Data proxy

I made the `data_proxy.py` file to create a Python application. I use the `paho-mqtt` library to make the script act as a MQTT publisher, the `aiocoap` library to make it act as a CoAP client and the `influxdb-client` library to store data.

Initially, through the MQTT protocol, the application gives commands, to the ESP32, to start the sensors reading and to set their sampling rate.

Periodically, through the CoAP protocol, the script requests, to the board, the latest collected indoor and outdoor temperature value. It continuously stores these values on a local InfluxDB instance.

The network latency, between the temperature value request (from the application to the ESP32) and its reception, is continuously monitored; after a while, the script evaluates the mean latency of this process.

C. Data analytics

I made the `data_analytics.py` file to create another Python application. I use the `influxdb-client` library to get and store data on the database, the `prophet` library to forecast future temperature values and the `paho-mqtt` library to make it act as a MQTT publisher.

At the beginning, the script gets all past temperature values from the database to make a prediction of some indoor and outdoor future values. As the forecasted temperature times are reached, the application stores the predicted values on the database.

Ciclically, the application retrieves some of the latest temperature values from the database and analyses them to check a possible HVAC waste. The alarm goes off if the variance of the latest indoor temperature values is above a certain threshold (1) (i.e. if the indoor temperature is changing rapidly) and if the mean of them is between the farthest of the latest indoor temperature values and the farthest of the latest outdoor ones (2) (i.e. if the indoor temperature is approaching the outdoor one). Mathematically speaking:

$$\text{var}(i_1, i_2, \dots, i_n) > \text{threshold} \quad (1)$$

$$\min(i_n, o_n) < \text{mean}(i_1, i_2, \dots, i_n) < \max(i_n, o_n) \quad (2)$$

where i is the indoor temperature, o is the outdoor temperature and t_1, t_2, \dots, t_n are the n latest temperature values retrieved: t_n is the farthest and t_1 is the newest. When the alarm goes off, the script stores the alarm event on the database and, through the MQTT protocol, gives the command, to the ESP32, to

turn on the LED; when the risk has passed, the script gives the command to turn it off.

The collected temperature values, together with the forecasted ones, and the counting of the alarm events are shown on a local Grafana instance, by means of a dashboard.

IV. RESULTS

A. Setup

To evaluate the performance of the system, I've experimented the following setup.

The data proxy application sets the indoor sensor to collect data every 3 seconds and the outdoor one every 20 seconds; it asks for them every 5 seconds. The mean network latency is evaluated after [an / 1] hour from the [start / beginning].

The data analytics script initially retrieves all temperature data from the database, for the forecasting, aggregating them every 15 seconds by the mean function: in this way, it gets more than 8000 indoor temperature values and as many outdoor. The application makes a prediction about the temperature of the next hour: it forecasts a value every 10 minutes, for 6 times. Every 30 seconds, the script retrieves the temperature values of the latest 2 minutes, without aggregating them, for the alarm check: the threshold, seen in (1), is [0.03].

B. [Evaluation / Experiment]

...

TABLE I
INDOOR FORECAST EVALUATION

Current Time	Observed Value	Forecasted Value		
		<i>yhat</i>	<i>yhat_lower</i>	<i>yhat_upper</i>
